Professur für Künstliche Intelligenz - Fakultät für Informatik

1 - Soft RL

Hard RL

• All methods seen so far search the optimal policy that maximizes the return:

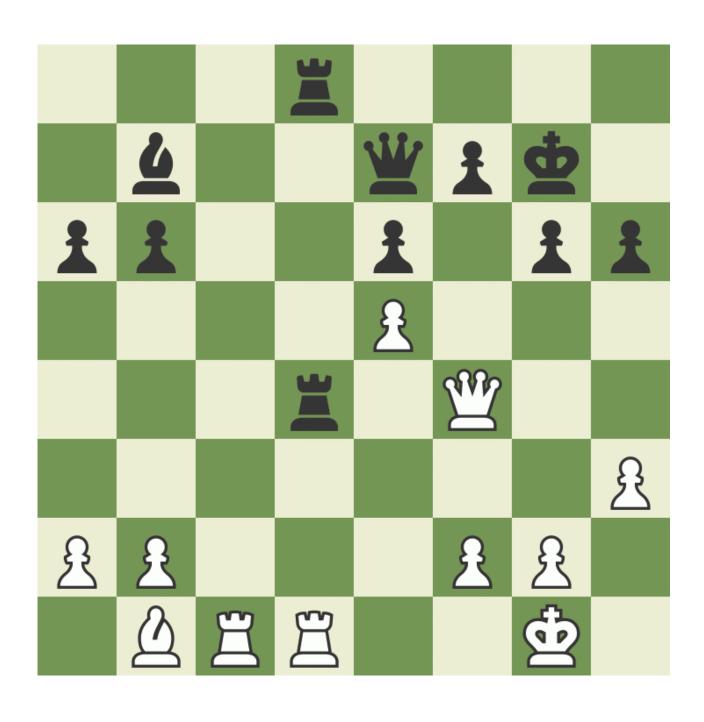

$$\pi^* = rg \max_{\pi} ~ \mathbb{E}_{\pi}[\sum_{t} \gamma^t ~ r(s_t, a_t, s_{t+1})]$$

• The optimal policy is deterministic and greedy by definition.

$$\pi^*(s) = rg \max_a Q^*(s,a)$$

- Exploration is ensured externally by :
 - applying ϵ -greedy or softmax on the Q-values (DQN),
 - adding exploratory noise (DDPG),
 - learning stochastic policies that become deterministic over time (A3C, PPO).
- Is "hard" RL, caring only about **exploitation**, always the best option?

Need for soft RL

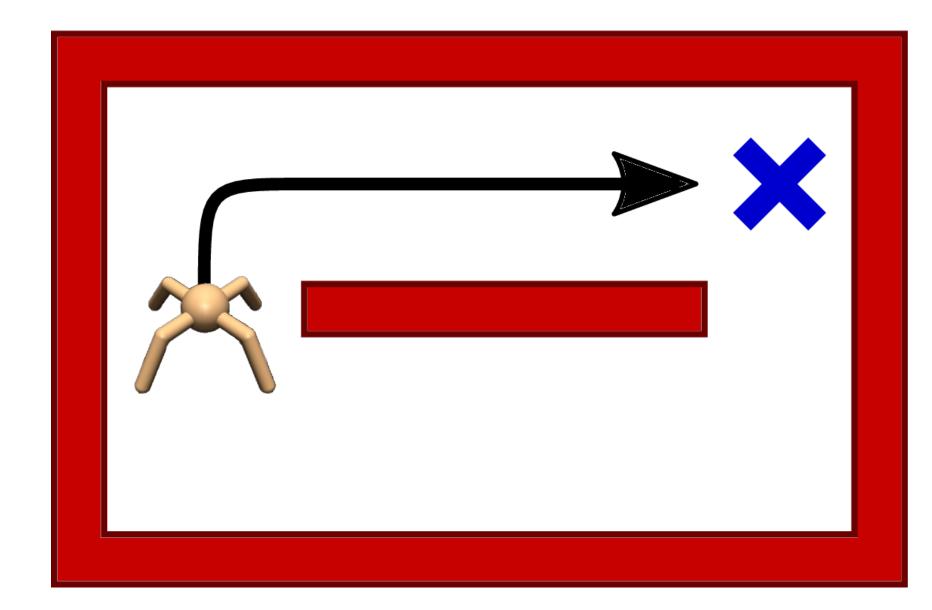

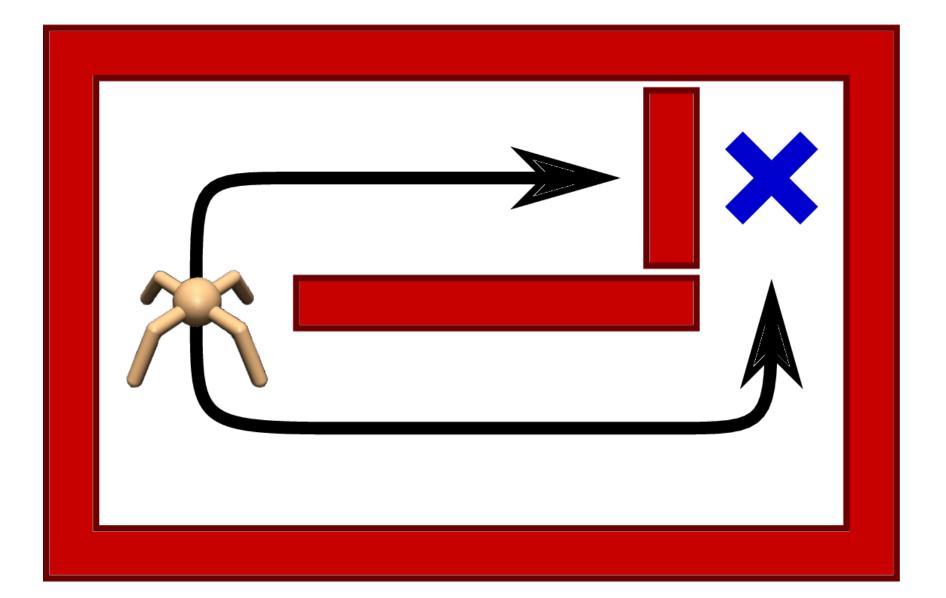

- The optimal policy is only greedy for a MDP, not obligatorily for a POMDP.
- Games like chess are POMDPs: you do not know what your opponent is going to play (missing information).
- If you always play the same moves (e.g. opening moves), your opponent will adapt and you will end up losing systematically.
- Variety in playing is beneficial in POMDPs: it can counteract the uncertainty about the environment.

Source: https://www.chess.com/article/view/announcing-the-chess-comgif-maker

Need for soft RL

- There are sometimes more than one way to collect rewards, especially with sparse rewards.
- If exploration decreases too soon, the RL agent will "overfit" one of the paths.
- If one of the paths is suddenly blocked, the agent would have to completely re-learn its policy.
- It would be more efficient if the agent had learned all possibles paths, even if some of them are less optimal.

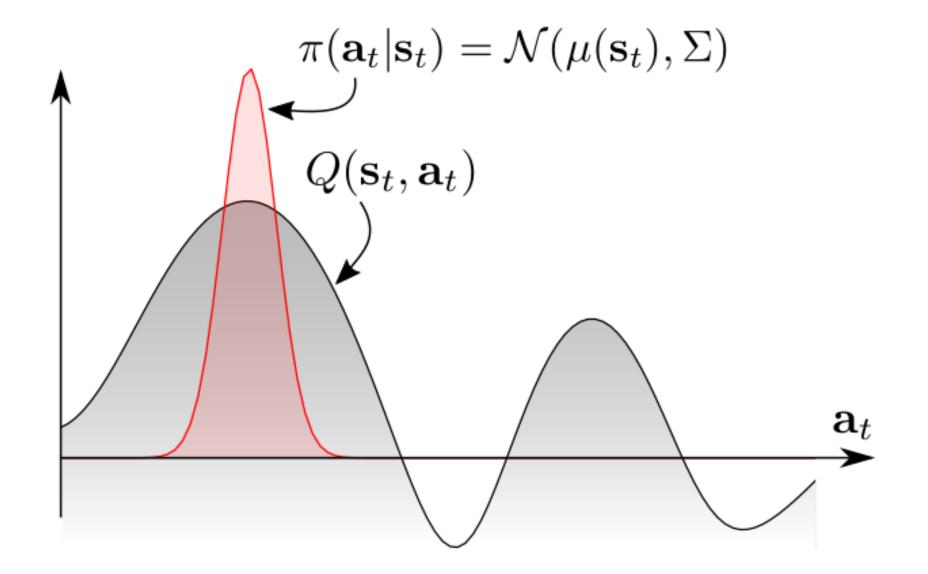

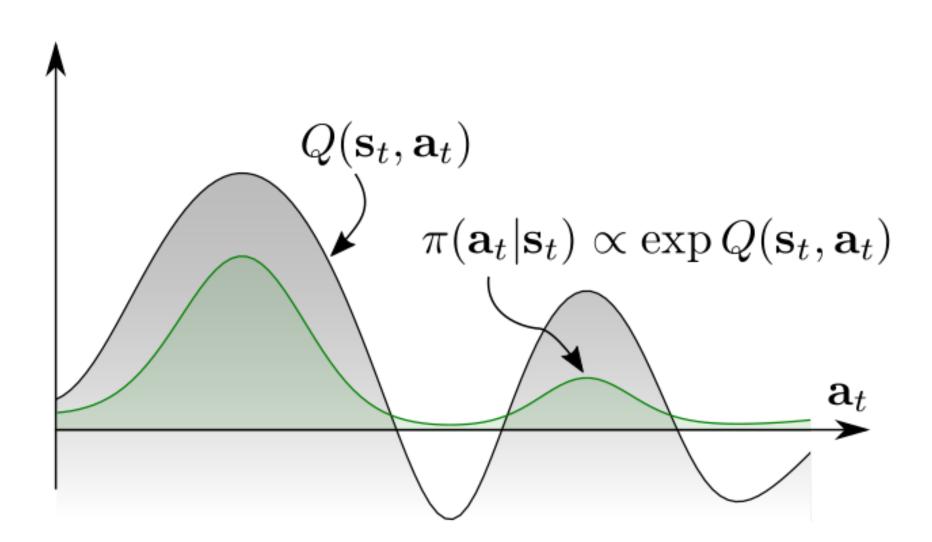

Need for soft RL

• Softmax policies allow to learn multimodal policies, but only for discrete action spaces.

$$\pi(s,a) = rac{\exp Q(s,a)/ au}{\sum_b \exp Q(s,b)/ au}$$

- In continuous action spaces, we would have to integrate over the whole action space, what is not tractable.
- Exploratory noise as in DDPG only leads to unimodal policies: greedy action plus some noise.

2 - Continuous stochastic policies

Gaussian policies

- The easiest to implement a stochastic policy with a neural network is a Gaussian policy.
- ullet Suppose that we want to control a robotic arm with n degrees of freedom.
- An action a is a vector of joint displacements:

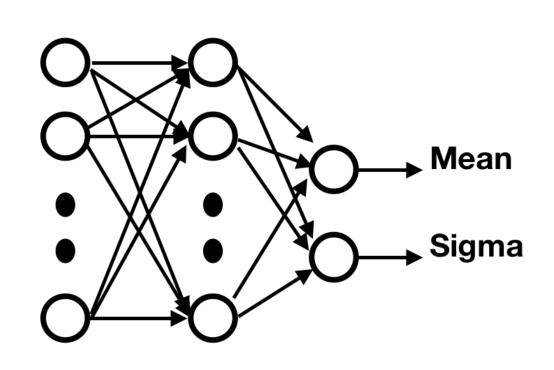

$$\mathbf{a} = egin{bmatrix} \Delta heta_1 & \Delta heta_2 & \dots \Delta heta_n \end{bmatrix}^T$$

- A Gaussian policy considers the vector ${f a}$ to be sampled from the **normal distribution** ${\cal N}(\mu_{ heta}(s),\sigma_{ heta}(s))$.
- The mean $\mu_{\theta}(s)$ and standard deviation $\sigma_{\theta}(s)$ are vectors that can be the output of the **actor** neural network with parameters θ .
- **Sampling** an action from the normal distribution is done through the **reparameterization trick**:

$$\mathbf{a} = \mu_{ heta}(s) + \sigma_{ heta}(s) \, \xi$$

where $\xi \sim \mathcal{N}(0,1)$ comes from the standard normal distribution.

https://medium.com/@vittoriolabarbera/continuouscontrol-with-a2c-and-gaussian-policies-mujocopytorch-and-c-4221ec8ba024

Gaussian policies

The good thing with the normal distribution is that we know its pdf:

$$\pi_{ heta}(s,a) = rac{1}{\sqrt{2\pi\sigma_{ heta}^2(s)}} \, \exp{-rac{(a-\mu_{ heta}(s))^2}{2\sigma_{ heta}^2(s)}}$$

• When estimating the **policy gradient** (REINFORCE, A3C, PPO, etc):

$$abla_{ heta} J(heta) = \mathbb{E}_{s \sim
ho^{\pi}, a \sim \pi_{ heta}} [
abla_{ heta} \log \pi_{ heta}(s, a) \, \psi]$$

the log-likelihood $\log \pi_{\theta}(s,a)$ is a simple function of $\mu_{\theta}(s)$ and $\sigma_{\theta}(s)$:

$$\log \pi_{ heta}(s,a) = -rac{(a-\mu_{ heta}(s))^2}{2\sigma_{ heta}^2(s)} - rac{1}{2}\,\log 2\pi\sigma_{ heta}^2(s)$$

so we can easily compute its gradient w.r.t θ and apply backpropagation:

$$abla_{\mu_{ heta}(s)} \log \pi_{ heta}(s,a) = rac{a - \mu_{ heta}(s)}{\sigma_{ heta}(s)^2} \qquad
abla_{\sigma_{ heta}(s)} \log \pi_{ heta}(s,a) = rac{(a - \mu_{ heta}(s))^2}{\sigma_{ heta}(s)^3} - rac{1}{\sigma_{ heta}(s)}$$

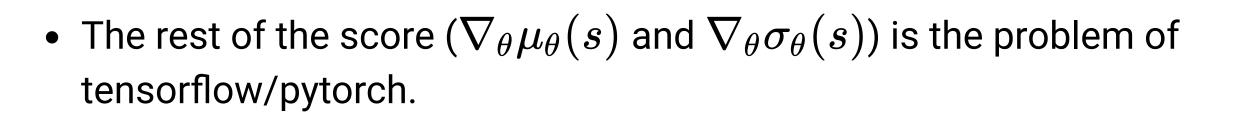

Gaussian policies

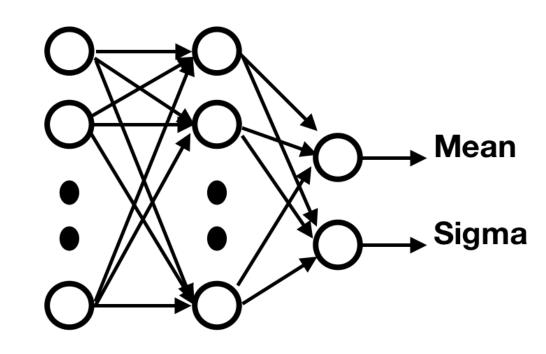

• A Gaussian policy samples actions from the **normal distribution** $\mathcal{N}(\mu_{\theta}(s), \sigma_{\theta}(s))$, with $\mu_{\theta}(s)$ and $\sigma_{\theta}(s)$ being the output of the actor.

$$\mathbf{a} = \mu_{ heta}(s) + \sigma_{ heta}(s) \, \xi$$

• The score $\nabla_{\theta} \log \pi_{\theta}(s,a)$ can be obtained easily using the output of the actor:

$$egin{aligned}
abla_{\mu_{ heta}(s)} \log \pi_{ heta}(s,a) &= rac{a - \mu_{ heta}(s)}{\sigma_{ heta}(s)^2} \
onumber \
abla_{\sigma_{ heta}(s)} \log \pi_{ heta}(s,a) &= rac{(a - \mu_{ heta}(s))^2}{\sigma_{ heta}(s)^3} - rac{1}{\sigma_{ heta}(s)} \end{aligned}$$

Source:

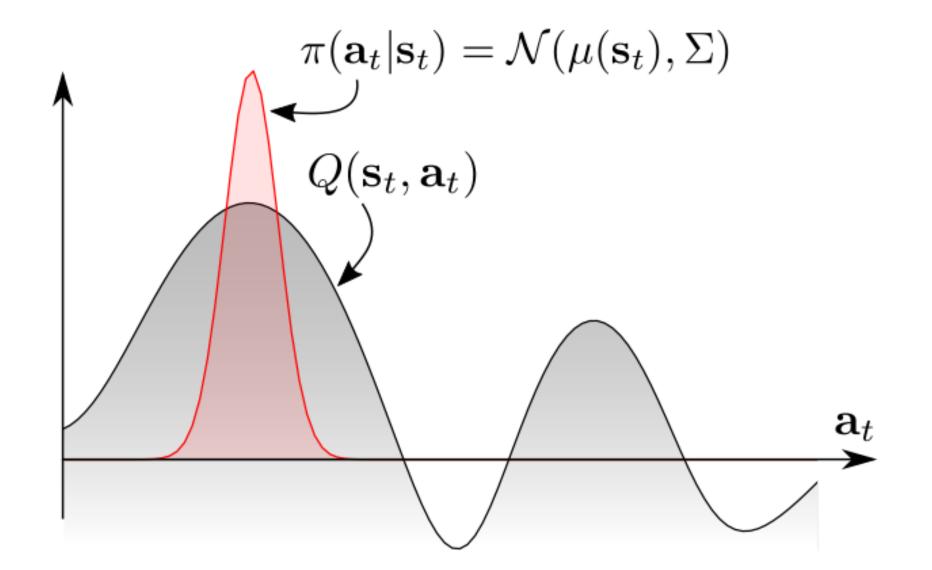

https://medium.com/@vittoriolabarbera/continuous-control-with-a2c-and-gaussian-policies-mujoco-pytorch-and-c-4221ec8ba024

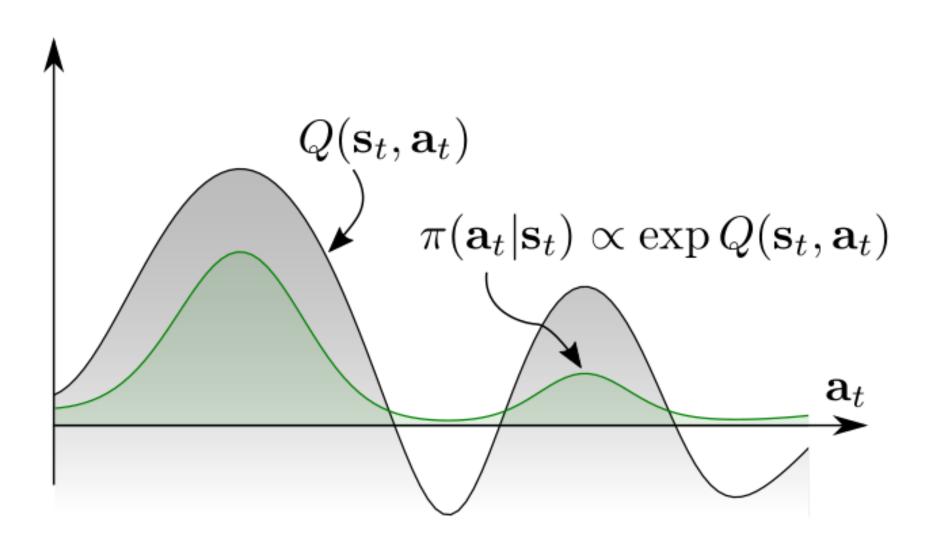

- This is the same reparametrization trick used in variational autoencoders to allow backpropagation to work through a sampling operation.
- Beta distributions are an even better choice to parameterize stochastic policies (Chou et al, 2017).

3 - Maximum Entropy RL

Soft policies

- Although stochastic, Gaussian policies are still **unimodal policies**: they mostly sample actions around the mean $\mu_{\theta}(s)$ and the variance $\sigma_{\theta}(s)$ decreases to 0 with learning.
- If we want a multimodal policy that learns different solutions, we need to learn a **Softmax** distribution (Gibbs / Boltzmann) over the action space.
- How can we do that when the action space is continuous?

Maximum Entropy RL

- A solution to force the policy to be **multimodal** is to force it to be as stochastic as possible by **maximizing its entropy**.
- Instead of searching for the policy that "only" maximizes the returns:

$$\pi^* = rg \max_{\pi} ~ \mathbb{E}_{\pi}[\sum_{t} \gamma^t ~ r(s_t, a_t, s_{t+1})]$$

we search for the policy that maximizes the returns while being as stochastic as possible:

$$\pi^* = rg \max_{\pi} \, \mathbb{E}_{\pi}[\sum_{t} \gamma^t \, r(s_t, a_t, s_{t+1}) + lpha \, H(\pi(s_t))]$$

- This new objective function defines the maximum entropy RL framework.
- The entropy of the policy **regularizes** the objective function: the policy should still maximize the returns, but stay as stochastic as possible depending on the parameter α .
- Entropy regularization can always be added to PG methods such as A3C.
- It is always possible to fall back to hard RL by setting lpha to 0.

Entropy of a policy

ullet The entropy of a policy in a state s_t is defined by the expected negative log-likelihood of the policy:

$$H(\pi_{ heta}(s_t)) = \mathbb{E}_{a \sim \pi_{ heta}(s_t)}[-\log \pi_{ heta}(s_t,a)]$$

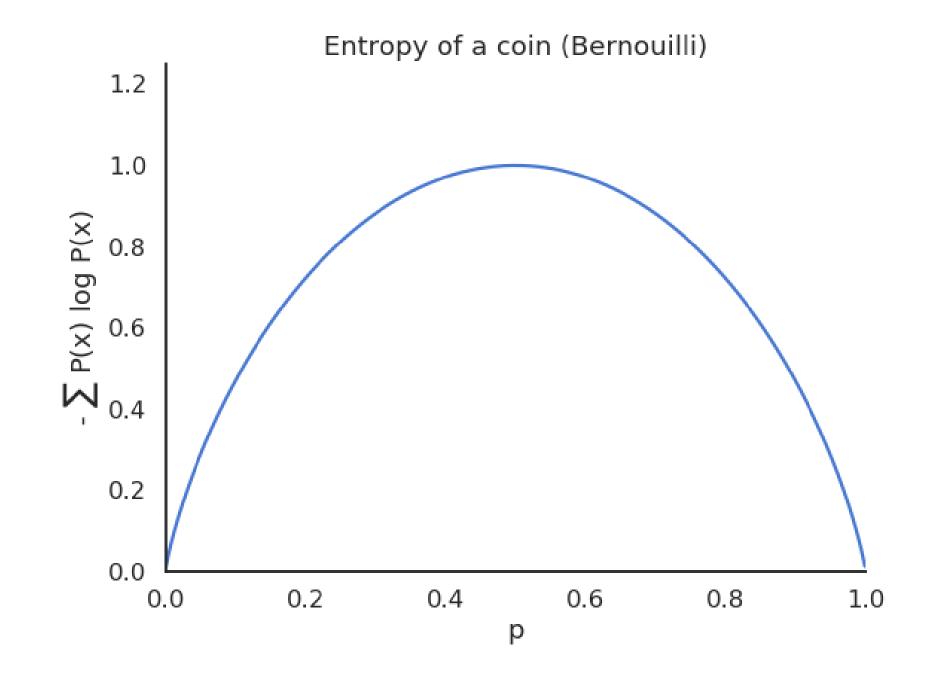

For a discrete action space:

$$H(\pi_{ heta}(s_t)) = -\sum_a \pi_{ heta}(s_t,a) \, \log \pi_{ heta}(s_t,a)$$

• For a continuous action space:

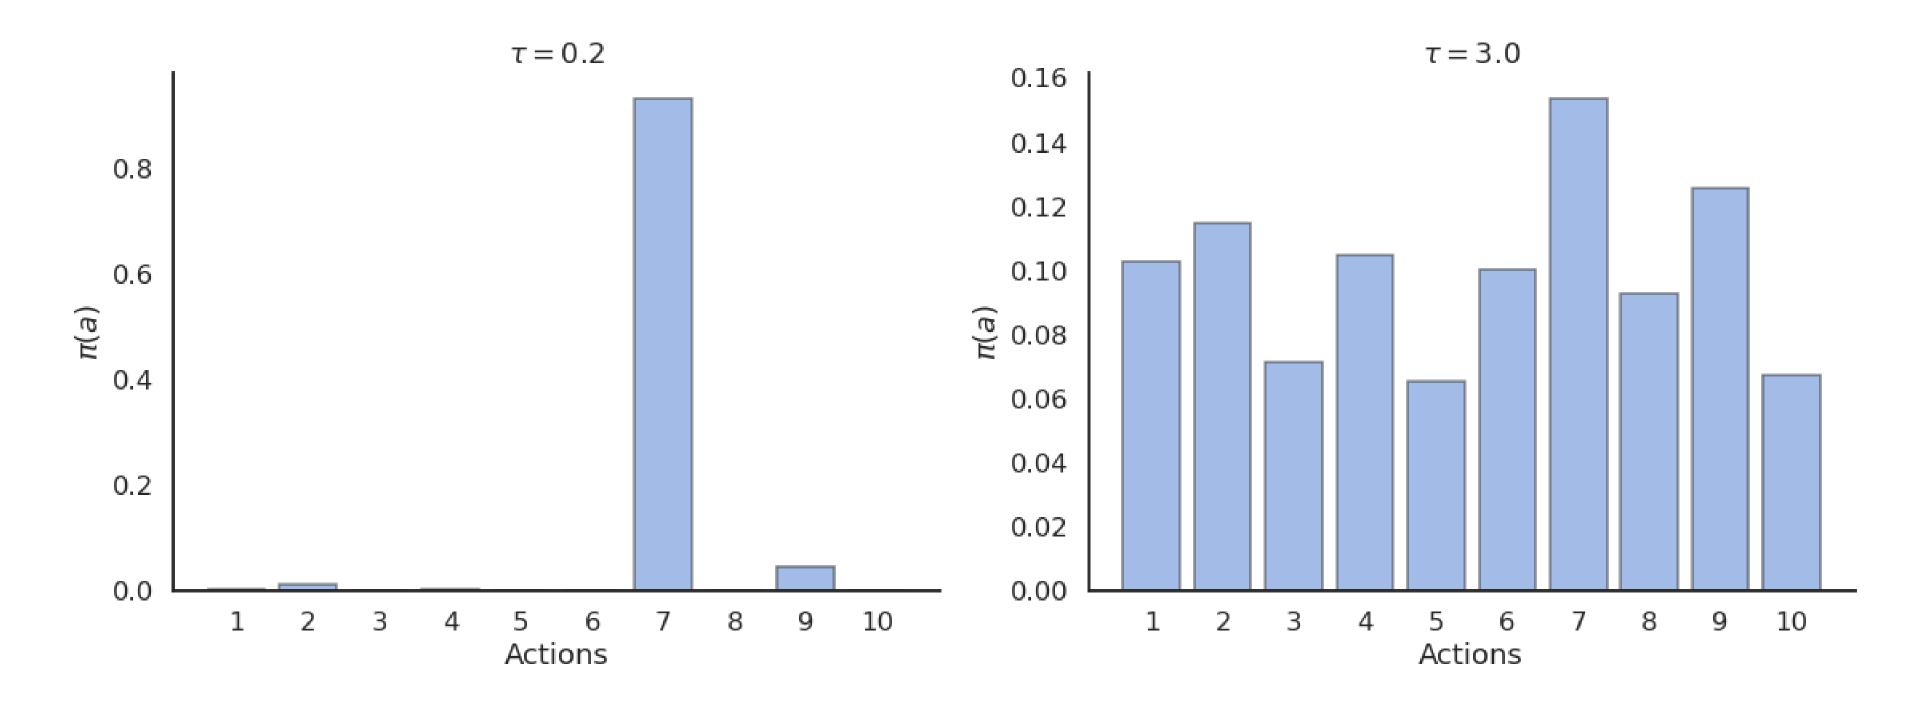

$$H(\pi_{ heta}(s_t)) = -\int_a \pi_{ heta}(s_t,a) \, \log \pi_{ heta}(s_t,a) \, da$$

 The entropy necessitates to sum or integrate the self-information of each possible action in a given state.

Entropy of a policy

- A **deterministic** (greedy) policy has zero entropy, the same action is always taken: **exploitation**.
- A **random** policy has a high entropy, you cannot predict which action will be taken: **exploration**.

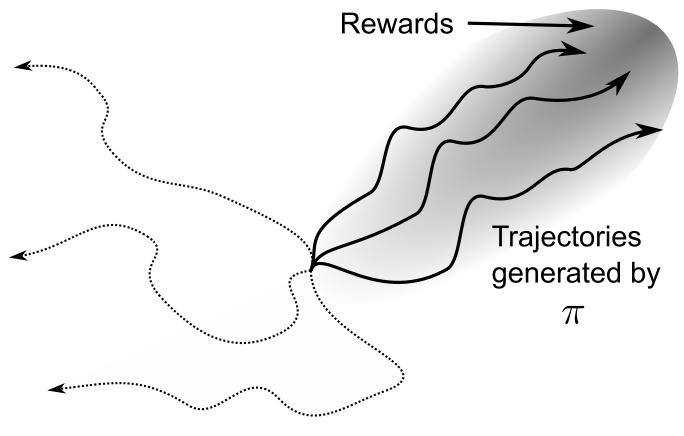

• Maximum entropy RL embeds the exploration-exploitation trade-off inside the objective function instead of relying on external mechanisms such as the softmax temperature.

Soft Q-learning

• In **soft Q-learning**, the objective function is defined over complete trajectories:

$$\mathcal{J}(heta) = \sum_t \gamma^t \, \mathbb{E}_{\pi}[r(s_t, a_t, s_{t+1}) + lpha \, H(\pi(s_t))]$$

- The goal of the agent is to generate trajectories associated with a lot of rewards (high return) but only visiting states with a high entropy, i.e. where the policy is random (exploration).
- The agent can decide how the trade-off is solved via regularization:
 - If a single action leads to high rewards, the policy may become deterministic.
 - If several actions lead to equivalent rewards, the policy must stay stochastic.

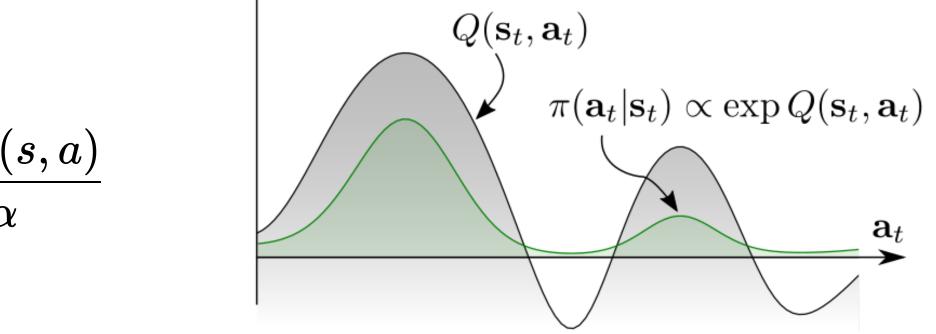

Any other possible trajectory

Soft Q-learning

 In soft Q-learning, the policy is implemented as a softmax over soft Q-values:

$$\pi_{ heta}(s,a) = rac{\exprac{Q_{ heta}^{ ext{soft}}(s,a)}{lpha}}{\sum_{b} \exprac{Q_{ heta}^{ ext{soft}}(s,b)}{lpha}} \propto \exprac{Q_{ heta}^{ ext{soft}}(s,a)}{lpha}$$

• α plays the role of the softmax temperature parameter τ .

- Soft Q-learning belongs to **energy-based models**, as $-\frac{Q_{\theta}^{\rm soft}(s,a)}{\alpha}$ represents the energy of the Boltzmann distribution (see restricted Boltzmann machines).
- The partition function $\sum_b \exp \frac{Q_\theta^{
 m soft}(s,b)}{lpha}$ is untractable for continuous action spaces, as one would need to integrate over the whole action space, but it will disappear from the equations anyway.

What are soft values?

• Soft V and Q values are the equivalent of the hard value functions, but for the new objective:

$$\mathcal{J}(heta) = \sum_t \gamma^t \, \mathbb{E}_{\pi}[r(s_t, a_t, s_{t+1}) + lpha \, H(\pi(s_t))]$$

• The soft value of an action depends on the immediate reward and the soft value of the next state (soft Bellman equation):

$$Q_{ heta}^{ ext{soft}}(s_t, a_t) = \mathbb{E}_{s_{t+1} \in
ho_{ heta}}[r(s_t, a_t, s_{t+1}) + \gamma \, V_{ heta}^{ ext{soft}}(s_{t+1})]$$

• The soft value of a state is the expected value over the available actions plus the entropy of the policy.

$$V_{ heta}^{ ext{soft}}(s_t) = \mathbb{E}_{a_t \in \pi}[Q_{ heta}^{ ext{soft}}(s_t, a_t)] + H(\pi_{ heta}(s_t)) = \mathbb{E}_{a_t \in \pi}[Q_{ heta}^{ ext{soft}}(s_t, a_t) - \log \, \pi_{ heta}(s_t, a_t)]$$

- Haarnoja et al (2017) showed that these soft value functions are the solution of the entropy-regularized objective function.
- All we need is to be able to estimate them... Soft Q-learning uses complex optimization methods (variational inference) to do it, but SAC is more practical.

4 - Soft Actor-Critic (SAC)

Soft Actor-Critic Algorithms and Applications

Tuomas Haarnoja*†‡ Aurick Zhou*† Kristian Hartikainen*† George Tucker‡

Sehoon Ha[‡] Jie Tan[‡] Vikash Kumar[‡] Henry Zhu[†] Abhishek Gupta[†]

Pieter Abbeel[†] Sergey Levine^{†‡}

Soft Actor-Critic (SAC)

• Putting these equations together:

$$egin{aligned} Q_{ heta}^{ ext{soft}}(s_t, a_t) &= \mathbb{E}_{s_{t+1} \in
ho_{ heta}}[r(s_t, a_t, s_{t+1}) + \gamma \, V_{ heta}^{ ext{soft}}(s_{t+1})] \ V_{ heta}^{ ext{soft}}(s_t) &= \mathbb{E}_{a_t \in \pi}[Q_{ heta}^{ ext{soft}}(s_t, a_t) - \log \, \pi_{ heta}(s_t, a_t)] \end{aligned}$$

we obtain:

$$Q_{ heta}^{ ext{soft}}(s_t, a_t) = \mathbb{E}_{s_{t+1} \in
ho_{ heta}}[r(s_t, a_t, s_{t+1}) + \gamma \, \mathbb{E}_{a_{t+1} \in \pi}[Q_{ heta}^{ ext{soft}}(s_{t+1}, a_{t+1}) - \log \, \pi_{ heta}(s_{t+1}, a_{t+1})]]$$

• If we want to train a **critic** $Q_{\varphi}(s,a)$ to estimate the true soft Q-value of an action $Q_{\theta}^{\rm soft}(s,a)$, we just need to sample $(s_t,a_t,r_{t+1},a_{t+1})$ transitions and minimize:

$$\mathcal{L}(arphi) = \mathbb{E}_{s_t, a_t, s_{t+1} \sim
ho_{ heta}}[(r_{t+1} + \gamma \, Q_{arphi}(s_{t+1}, a_{t+1}) - \log \pi_{ heta}(s_{t+1}, a_{t+1}) - Q_{arphi}(s_t, a_t))^2]$$

- The only difference with a SARSA critic is that the negative log-likelihood of the next action is added to the target.
- In practice, s_t , a_t and r_{t+1} can come from a replay buffer, but a_{t+1} has to be sampled from the current policy π_{θ} (but not taken!).
- SAC is therefore an off-policy actor-critic algorithm, but with stochastic policies!

Soft Actor-Critic (SAC)

ullet But how do we train the actor? The policy is defined by a softmax over the soft Q-values, but the log-partition Z is untractable for continuous spaces:

$$\pi_{ heta}(s,a) = rac{\exprac{Q_{arphi}(s,a)}{lpha}}{\sum_{b}\exprac{Q_{arphi}(s,b)}{lpha}} = rac{1}{Z}\,\exprac{Q_{arphi}(s,a)}{lpha}$$

• The trick is to make the **parameterized actor** π_{θ} learn to be close from this softmax, by minimizing the KL divergence:

$$\mathcal{L}(heta) = D_{ ext{KL}}(\pi_{ heta}(s,a) || rac{1}{Z} \, \exp rac{Q_{arphi}(s,a)}{lpha}) = \mathbb{E}_{s,a \sim \pi_{ heta}(s,a)} [-\log rac{rac{1}{Z} \, \exp rac{Q_{arphi}(s,a)}{lpha}}{\pi_{ heta}(s,a)}]$$

ullet As Z does not depend on heta, it will automagically disappear when taking the gradient!

$$abla_{ heta} \, \mathcal{L}(heta) = \mathbb{E}_{s,a} [lpha \,
abla_{ heta} \log \pi_{ heta}(s,a) - Q_{arphi}(s,a)]$$

• So the actor just has to implement a Gaussian policy and we can train it using soft-Q-value.

Soft Actor-Critic (SAC)

• Soft Actor-Critic (SAC) is an off-policy actor-critic architecture for maximum entropy RL:

$$\mathcal{J}(heta) = \sum_t \gamma^t \, \mathbb{E}_{\pi}[r(s_t, a_t, s_{t+1}) + lpha \, H(\pi(s_t))]$$

- Maximizing the entropy of the policy ensures an efficient exploration. It is even possible to learn the value of the parameter α .
- The critic learns to estimate soft Q-values that take the entropy of the policy into account:

$$\mathcal{L}(arphi) = \mathbb{E}_{s_t, a_t, s_{t+1} \sim
ho_{ heta}}[(r_{t+1} + \gamma \, Q_{arphi}(s_{t+1}, a_{t+1}) - \log \pi_{ heta}(s_{t+1}, a_{t+1}) - Q_{arphi}(s_t, a_t))^2]$$

• The actor learns a Gaussian policy that becomes close to a softmax over the soft Q-values:

$$\pi_{ heta}(s,a) \propto \exprac{Q_{arphi}(s,a)}{lpha}
onumber$$
 $abla_{ heta}\mathcal{L}(heta) = \mathbb{E}_{s,a}[lpha\,
abla_{ heta}\log\pi_{ heta}(s,a) - Q_{arphi}(s,a)]$

SAC vs. TD3

- In practice, SAC uses **clipped double learning** like TD3: it takes the lesser of two evils between two critics Q_{φ_1} and Q_{φ_2} .
- The next action a_{t+1} comes from the current policy, no need for target networks.
- Unlike TD3, the learned policy is **stochastic**: no need for target noise as the targets are already stochastic.
- See https://spinningup.openai.com/en/latest/algorithms/sac.html for a detailed comparison of SAC and TD3.
- The initial version of SAV additionally learned a soft V-value critic, but this turns out not to be needed.

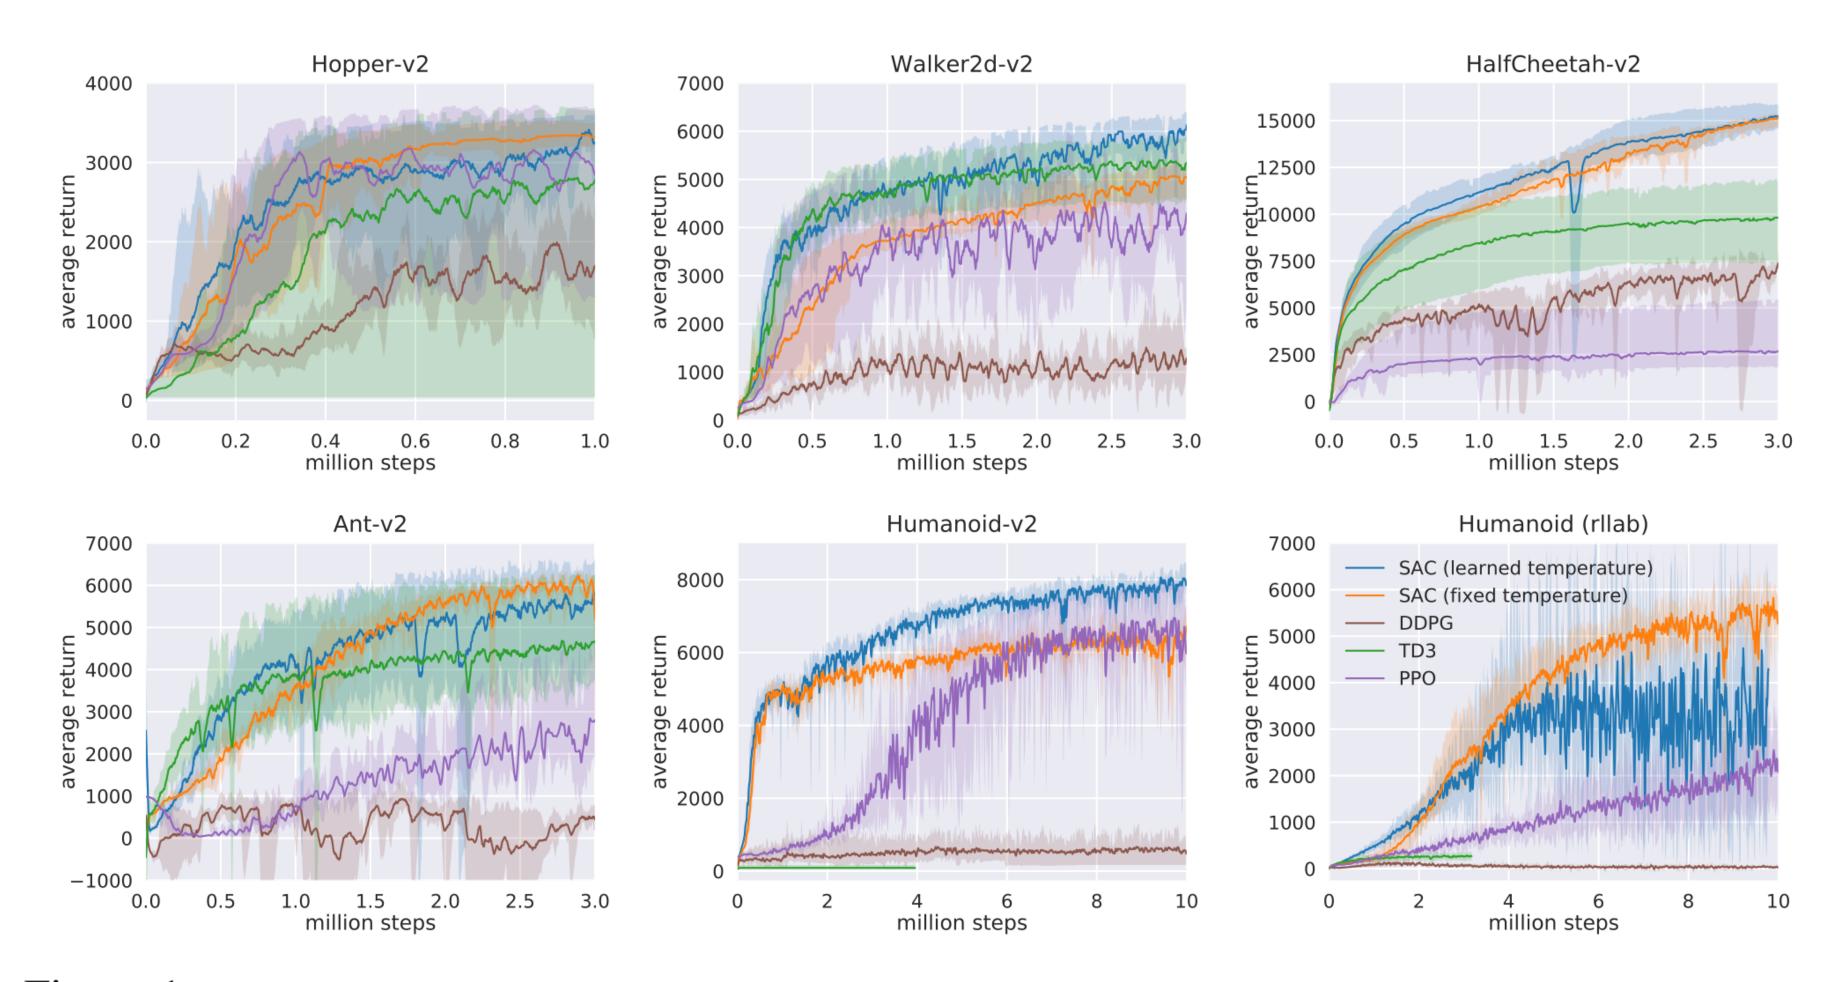

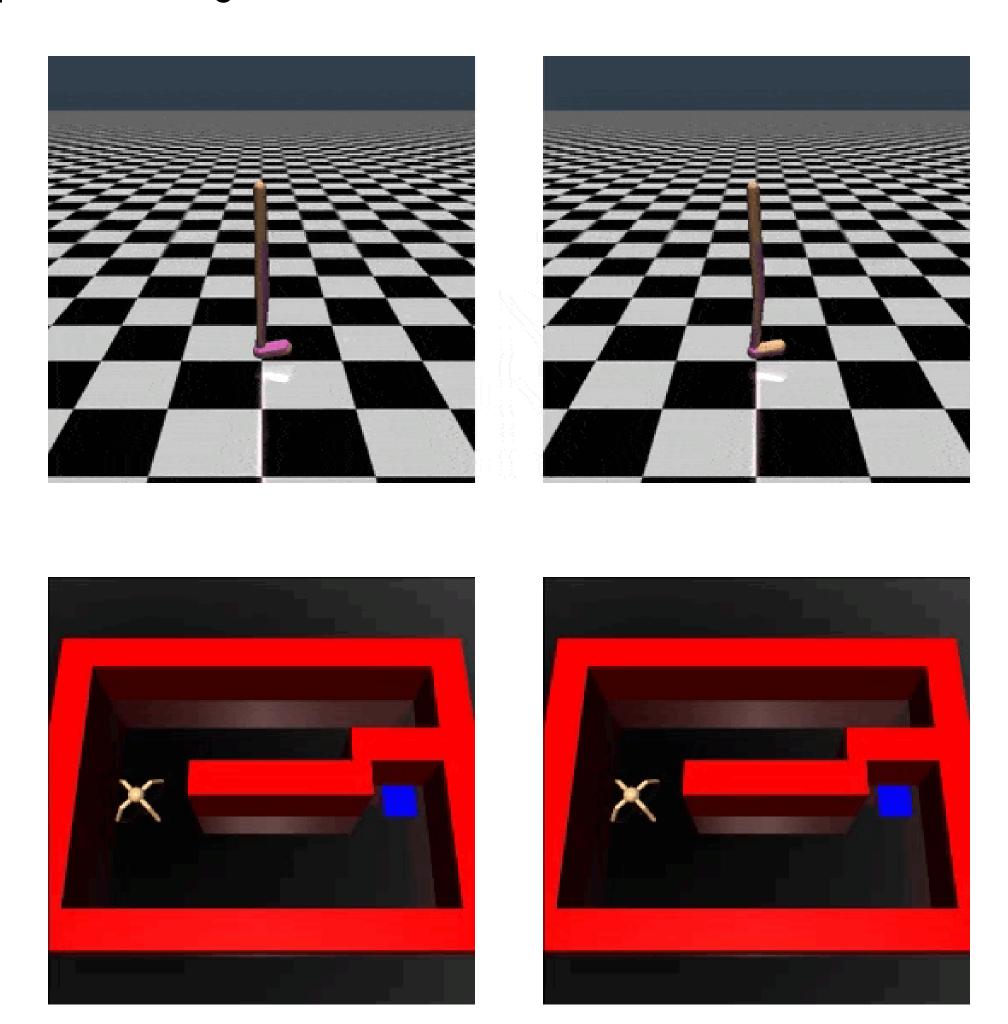

Figure 1: Training curves on continuous control benchmarks. Soft actor-critic (blue and yellow) performs consistently across all tasks and outperforming both on-policy and off-policy methods in the most challenging tasks.

SAC results

• The enhanced exploration strategy through maximum entropy RL allows to learn robust and varied strategies that can cope with changes in the environment.

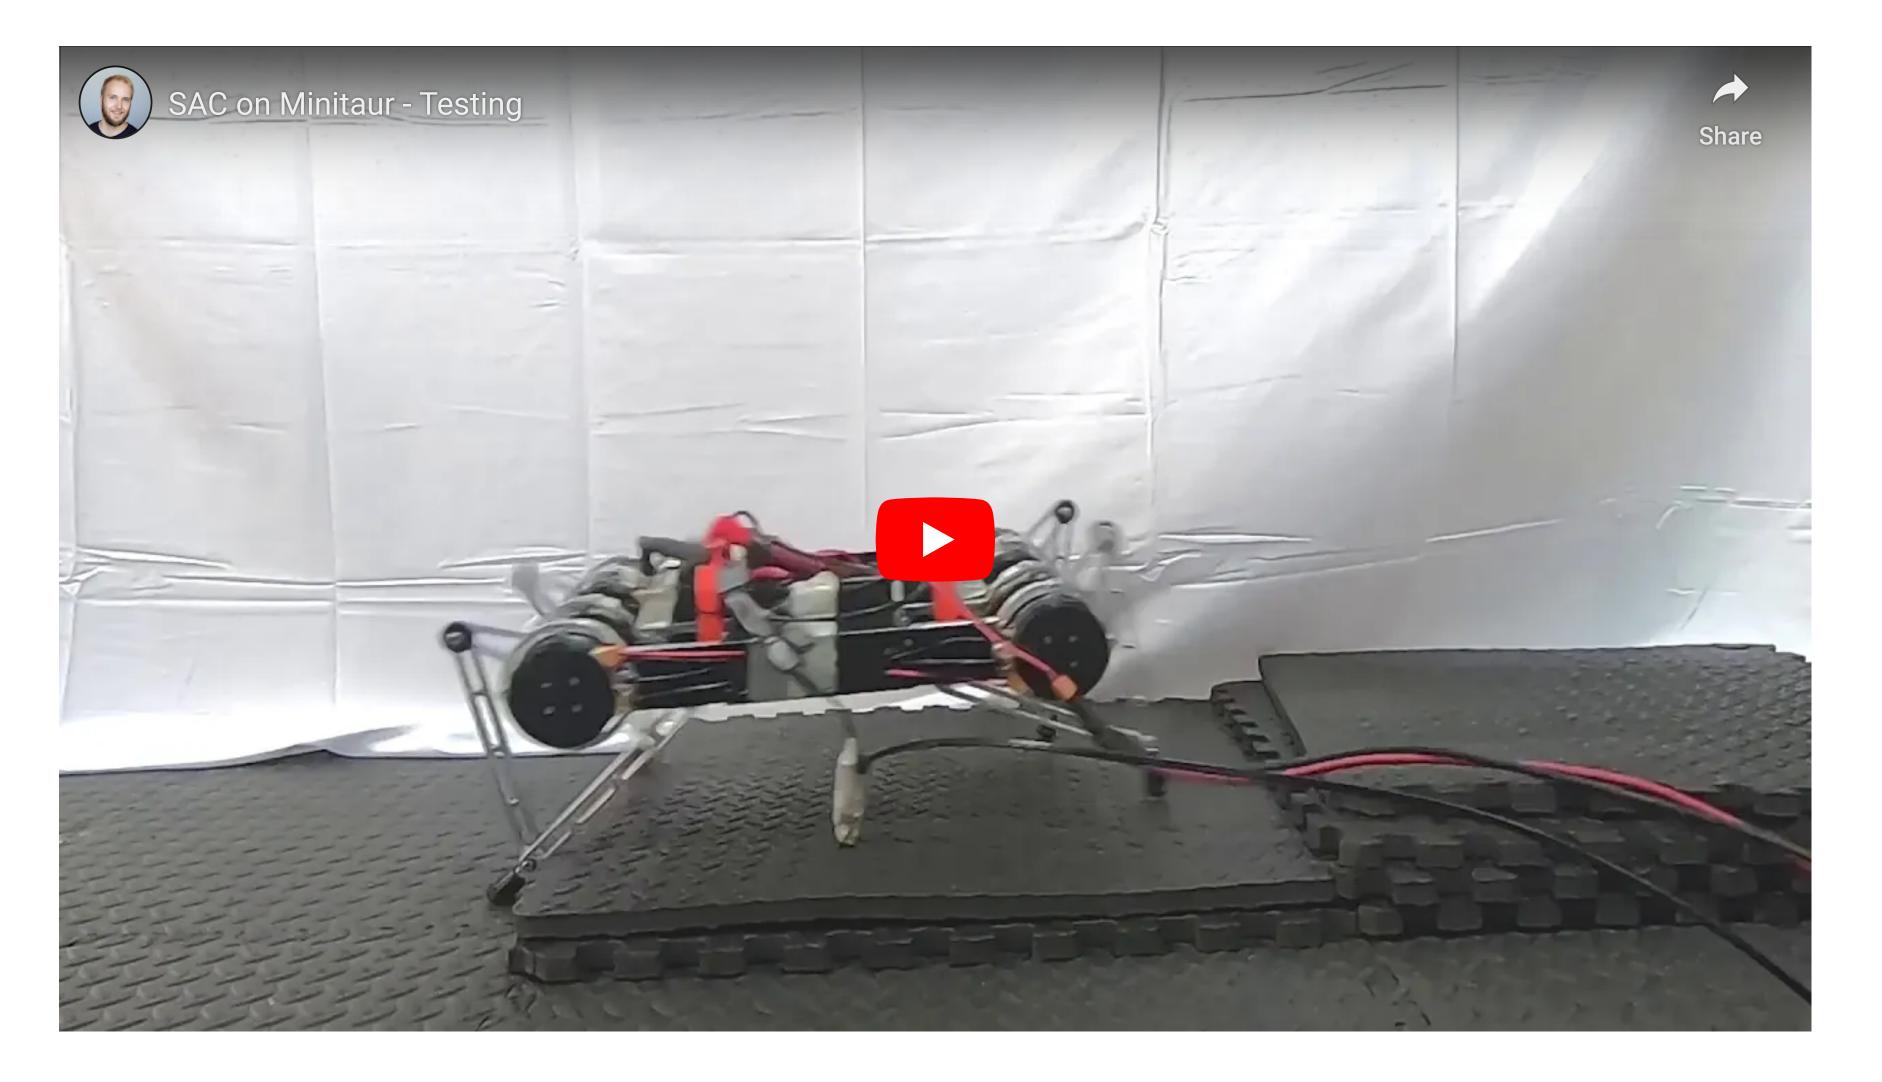

Real-world robotics

• The low sample complexity of SAC allows to train a real-world robot in less than 2 hours!

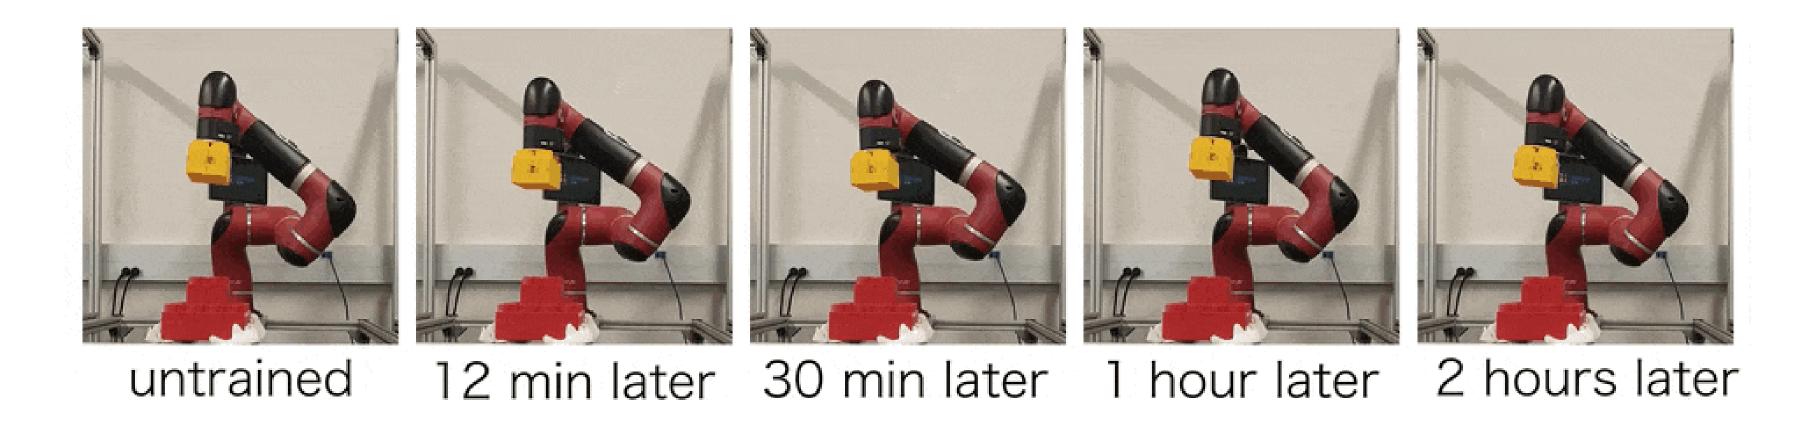

Real-world robotics

• Although trained on a flat surface, the rich learned stochastic policy can generalize to complex terrains.

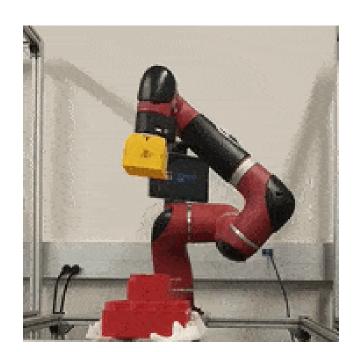

Real-world robotics

• When trained to stack lego bricks, the robotic arm learns to explore the whole state-action space.

• This makes it more robust to external perturbations after training:
